Clicking hip in a postmenopausal woman

Len Kelly MD MCiSc, Rajiv Gandhi MD, Aunkul Panu MD

A 55-year-old postmenopausal woman experiences intermittent anterior clicking and locking of her hip while walking. The clicking is painful and comes on without warning, causing her to stop walking for several minutes. The patient has no history of trauma and no night pain. She enjoys golf, but now has to ride in a golf cart to complete the round. Initial examination shows a normal range of motion without pain. There is no evidence of femoral or inguinal hernia or localized tenderness consistent with a trochanteric bursitis. Radiographs of her hip appear normal.

What causes of pain should be considered?
The patient’s history of intermittent symptoms indicates a mechanical origin of pain. That the patient had normal range of motion without pain on examination is a pertinent negative finding for osteoarthritis. Because there was no evidence of osteoarthritis or metastatic disease on the plain radiographs, nor evidence of hernia (femoral or inguinal), trochanteric bursitis or local inflammation or infection on examination, a labral tear of the cartilage of the acetabulum should be considered.

A labral tear occurs at the relatively avascular proximal portion of the cartilaginous labrum where it attaches to the articular cartilage of the hip joint. It typically presents as anterior mechanical hip pain.

The labrum acts as a seal of the synovial fluid and extends the depth of the joint by as much as 25%. Pivoting in activities such as golf, hockey, soccer and ballet may cause tears.1,2 Two common types of tears are described: traumatic tears (young athletes) and degenerative tears (early osteoarthritis in older patients).1,3

Labral tears may be asymptomatic. In a study involving 70 asymptomatic individuals (mean age 26 yr), a surprising 27 (39%) cases of labral tear seen on high-resolution magnetic resonance (MR) imaging were reported.4

Does this patient require any additional assessment on examination?
The clinical assessment for a labral tear involves evocative rotational end-point testing of a flexed hip. This test comprises stressing a 90° flexed hip both in abduction and adduction, and adding internal and external rotation to pinch the torn labrum between the femoral head and acetabular rim (a useful video of how to do a hip examination for a labral tear is available at www.youtube.com/watch?v=Rtp4oz0_3YY). Although painful or palpable clicking may indicate the presence of a labral tear, the physical exam shows low specificity.3

What investigations are required if a labral tear is suspected?
An MR arthrogram involving injection of contrast medium into the joint is typically used to identify labral tears5 (Figure 1). Because a labral tear dis-

rupts the seal of the synovial fluid within the joint, extravasation of the contrast medium shows the location and extent of the tear. For patients averse to intra-articular injection, high-resolution MR imaging may be a good substitute.6

If imaging shows a labral tear, what are the treatment options for this patient?

In this older patient, damage of the adjacent articular cartilage in her hip joint is likely, and labral débridement may not give definitive symptom relief.

Uncontrolled studies have shown that discrete sports-related labral tears may respond to arthroscopic hip surgery in younger athletic patients.7 However, a Canadian study involving 41 older patients (> 45 yr; mean age 53.7 yr) showed poor results of surgery, with relatively high reoperation rates and minimal improvement in joint-specific and overall quality-of-life measures.8 The authors of a similar American study involving 30 patients (mean age 63.9 yr) also recommend caution in advising surgery in older patients because of poor two-year overall survival (70%) and a reoperation rate of 37%, most often requiring total hip arthroplasty.9

In this patient’s age group, a labral tear may be a sign of a deteriorating joint rather than an isolated repairable lesion. Watchful waiting and non–load-bearing exercise may be a good option. Physiotherapy techniques currently include active and deep-tissue release in addition to progressive resisted stretching and strengthening activities.1

Poor response to conservative treatment and increasing disability may require revisiting surgery as a treatment option.

Case revisited

On further examination, rotational testing of the patient’s flexed hip reproduced a painful click. The patient decided to proceed with an MR arthrogram, which showed a labral tear. Given the poor results of surgery in her age group, the patient decided not to consider surgery at this point and will seek conservative treatment with physiotherapy to maximize her overall flexibility and strength.

Decisions is a series that focuses on practical evidence-based approaches to common presentations in primary care. The articles address key decisions that a clinician may encounter during initial assessment. The information presented can usually be covered in a typical primary care appointment. Articles should be no longer than 650 words, may include one box, figure or table and should begin with a very brief description (75 words or less) of the clinical situation. The decisions addressed should be presented in the form of questions. A box providing helpful resources for the patient or physician is encouraged.
