

Polypharmacy and clinical outcomes

I read with interest the article by Lu and colleagues¹ which shows that quality indicators of pharmacotherapy are associated with increased odds of admission to hospital, but reduced odds of death. However, some problems in the analysis may explain the results. Specifically, based on Tables 1 and 3, there are 15 102 patients without use of drugs included in the analysis of the effects of potentially inappropriate medications (PIMs) and anticholinergic burden on the outcomes but not included in the analysis of polypharmacy. Because of the high mortality of these patients (91.6%), they may not be representative of general older adults. If these patients are excluded, the mortality rates in patients without the use of PIMs or anticholinergics are much lower than those in the original reports (24.6% v. 56.2% and 21.3% v. 41.9%, respectively).

The authors respond

We very much appreciate Shen's¹ interest in our paper,² however, Shen's comments are misleading.

First, Shen's recalculation of the number of patients who had a death event in Table 3, using data from Table 1, was incorrect. Our study is longitudinal, with up to 10 years of follow-up. Table 1 represents drug exposure at baseline and Table 3 represents exposure during follow-up. Therefore, direct calculation between these two tables is improper. Shen has recalculated the original data from Tables 1 and 3, and this approach results in a misinterpretation of our data.

Second, as our study is longitudinal with repeated measurements (up to

40 quarters), the event numbers of all-cause and fracture-specific admissions could be larger than the patient numbers, meaning a patient could experience more than one all-cause or fracture-specific admission during the follow-up period. That is also the reason we adopt generalized estimating equation (GEE) models with an autoregressive correlation structure to fit our study design. The "no. of patients" in Table 3 is actually "no. of patients who experience a clinical event in an observational time unit" (3 mo in our study), under the framework of GEE models.

Canadian Task Force obesity guidelines are unbalanced

As an academic group of bariatric surgeons, we are disappointed that the Canadian Task Force guidelines¹ did not balance the rather depressing evidence for the limited effectiveness of medical and lifestyle interventions in severe obesity, with the dramatic evidence in support of bariatric surgery. In appropriately selected patients, bariatric surgery is not only remarkably safe, but has the potential to achieve durable regression and remission of many obesity-related

esollia/Stock

comorbidities such as type 2 diabetes, hypertension, sleep apnea, and even cancer. To not present a balanced picture of the care available to the obese patient is a disservice and to misrepresent the evidence for bariatric surgery in patients with severe obesity is unfortunate.

The authors respond

We thank de Gara and colleagues' for their letter.¹ Given the high prevalence of adult overweight and obesity in Canada, there was an urgent need to review evidence for primary care, the core focus of the Canadian Task Force on Preventive Health Care recommendations.²

We did not misrepresent the benefits of bariatric surgery: bariatric surgery is effective for the treatment of severe obesity and we did not state otherwise.

Rather, in the associated systematic treatment review in *CMAJ Open*³ we specifically excluded bariatric surgery from consideration.
