

WHAT IS YOUR CALL?

An 82-year-old man with ataxia and dysarthria

Lilian L.Y. Vivas MD, Wayne L. Gold MD, Daniel M. Mandell MD, Peter E. Wu MD

An 82-year-old man presented to the emergency department with a two-week history of imbalance and gait disturbance resulting in a fall 10 days before presentation. There was no head injury. He previously walked without restriction, but on presentation he required a two-wheeled walker to maintain balance. He also reported a two-day history of dysarthria.

Eleven weeks prior, he was diagnosed with an infected ulcer overlying the plantar aspect of his right first metatarsal head. He had a history of type 2 diabetes mellitus and peripheral arterial disease. Treatment was started with ceftriaxone 1 g intravenously every 24 hours and metronidazole 500 mg orally every 12 hours.

Other medical history included coronary artery disease, congestive heart failure, atrial fibrillation, stage 3 chronic kidney disease (estimated glomerular filtration rate 45 mL/min), hypothyroidism, anxiety and gout. He did not smoke or consume alcohol. Medications on presentation are listed in Box 1.

On examination, he was afebrile with a blood pressure of 147/83 mm Hg and a heart rate of 66 beats/min that was irregularly irregular. Cardiovascular examination was otherwise normal. He had normal respiratory and abdominal examinations. Peripheral vascular examination revealed a noninfected, healing ulcer on the plantar aspect of his right foot. On neurologic examination, there was no nuchal rigidity. His mental status was normal. On language function, there was no evidence of word-finding difficulty and comprehension was normal. Cranial nerve examination revealed dysarthric speech. Articulation was impaired and his consonants were dulled. Motor examination was normal with the exception of reduced ankle reflexes (1+) bilaterally. Sensory examination revealed decreased light touch and pinprick to the midcalves as well as diminished vibration and proprioception. He had an unsteady, wide-based gait requiring a two-person assist to prevent him from falling. There was no dysidiadochokinesia or dysmetria.

Complete blood count and electrolyte measurements were normal. His serum creatinine level was 141 (normal 64–110) $\mu\text{mol/L}$, hemoglobin A_{1c} level was 8.7% and international normalized ratio was 2.19. Electrocardiography showed atrial fibrillation and a right bundle branch block, which was unchanged from previous recordings. Non-enhanced computed tomography (CT) of the brain showed chronic ischemic changes in the cerebral white matter without evidence of acute intracranial abnormalities.

Box 1: List of patient medications on presentation to the emergency department

Medication	Dosage
Insulin lispro protamine/insulin lispro	75%/25% mixture subcutaneously twice daily
Amlodipine	5 mg orally daily
Candesartan	4 mg orally daily
Hydralazine	5 mg orally twice daily
Metoprolol	12.5 mg orally twice daily
Warfarin	5 mg orally daily
Ezetimibe	10 mg orally daily
Omeprazole	20 mg orally daily
Levothyroxine	0.1 mg orally daily
Sertraline	100 mg orally daily
Ceftriaxone	1 g intravenously daily
Metronidazole	500 mg orally twice daily

KEY POINTS

- Metronidazole-induced encephalopathy is a rare idiosyncratic reaction.
- Most cases resolve with discontinuation of metronidazole.
- Idiosyncratic drug reactions are unpredictable and difficult to diagnose.
- New and unexplained symptoms following treatment with a new medication merit consideration of an adverse reaction.
- Identifying adverse drug reactions will help to mitigate consequences and prevent re-exposure.

Given his presentation of subacute ataxia and dysarthria with nondiagnostic CT, the patient was admitted to hospital for further investigation and management.

What are the next steps?

- Lumbar puncture with cerebrospinal fluid analysis
- Electromyography and nerve conduction studies
- Magnetic resonance imaging (MRI) of the brain
- Supportive physical and occupational therapy

The correct answers are (c) MRI of the brain and (d) supportive physical and occupational therapy. This patient's signs and symptoms localize to the posterior circulation and cerebellum. Compared with CT, MRI provides greater detail for examination of the structures of the posterior fossa, and characterizing pathology in this territory would be the most appropriate next step.

The MRI revealed bilaterally symmetric hyperintensity in the dentate nuclei of the cerebellum and in the splenium of the corpus callosum on T_2 -weighted fluid-attenuated inversion recovery (FLAIR) images (Figure 1). There were also chronic ischemic changes in the periventricular and deep white matter of the cerebral hemispheres as previously shown on CT, a common finding related to advanced age and vascular risk factors.

In consideration of his functional impairment and falls, supportive physical and occupational therapy (d) was also initiated to aid in his daily activities. Lumbar puncture and cerebrospinal fluid

analysis (a) was not performed on presentation because the patient was afebrile and not immunocompromised, lowering the suspicion for infection. Although infections of the central nervous system can present with cerebellar symptoms and without fever, a lumbar puncture was not chosen as one of the immediate next steps but would be part of a second tier of investigations if the MRI were nondiagnostic. Lastly, although there was evidence of diabetic sensory neuropathy on examination, electromyography and nerve conduction studies (b) would not assist in the diagnosis of his dysarthria.

Based on the findings on MRI, what is the most likely diagnosis?

- Multiple sclerosis
- Infectious encephalopathy
- Toxic encephalopathy
- Alzheimer dementia

The cerebellar abnormalities on MRI conform to the dentate nuclei rather than a particular vascular territory, which argues against infarction as a cause. These MRI findings are inconsistent with multiple sclerosis (a), because demyelination tends to preferentially affect white matter more than grey matter (nuclei). The symmetry of the imaging findings, as well as involvement of the dentate nuclei and splenium of the corpus callosum, suggests either a metabolic, toxic, infectious or neurodegenerative process.^{1,2} With normal cognition, the absence of volume loss on neuroimaging and

Figure 1: Axial T_2 -weighted fluid-attenuated inversion recovery (FLAIR) magnetic resonance images showing (A) bilaterally symmetric hyperintensity in the dentate nuclei of the cerebellum (arrows), and (B) splenium of the corpus callosum (long arrows) and chronic ischemic changes in the cerebral white matter (short arrows).

normal-sized ventricles, Alzheimer dementia (d) is unlikely. Infectious encephalopathy (b) is still a consideration.

Given this patient's medication exposure and MRI findings, the leading diagnosis is (c) toxic encephalopathy secondary to metronidazole, also known as metronidazole-induced encephalopathy. The most common imaging finding of metronidazole-induced encephalopathy is symmetric hyperintensity on T_2 -weighted images in the dentate nuclei.^{2,3} The splenium of the corpus callosum, periaqueductal grey matter and dorsal brainstem are often also involved.^{3,4} Less commonly, there is abnormality in the cerebral hemispheric white matter or basal ganglia.⁴ This patient had received metronidazole for 11 weeks for his foot ulcer, with a total cumulative dose of more than 80 g.

At the time of our assessment, his ulcer no longer appeared infected; therefore, both the ceftriaxone and the metronidazole were stopped. Seven days following the discontinuation of the metronidazole, he showed marked improvement of his cerebellar symptoms to the point that he could ambulate without assistance, and his speech had returned to normal. One month following discontinuation of his metronidazole he had complete resolution of his cerebellar signs and symptoms, supporting the diagnosis of metronidazole-induced encephalopathy. This diagnosis is further substantiated with application of the Naranjo Adverse Drug Reaction Probability Scale. The

patient scored 7 on the scale, suggesting a probable adverse drug reaction (Box 2).⁵

Discussion

Metronidazole is a 5-nitroimidazole antimicrobial with activity against protozoa and anaerobic bacteria.³ Reduction of metronidazole produces reactive metabolites, which result in disruption of the DNA of microbial cells, culminating in cell death.³ Although metronidazole is generally well-tolerated with broad clinical utility, it is known to cause idiosyncratic neurologic reactions, specifically peripheral sensory neuropathy and encephalopathy.³ Though rare, both of these reactions can result in substantial functional impairment, and merit appropriate counselling and monitoring.

Clinical features of metronidazole-induced encephalopathy

Metronidazole-induced encephalopathy is a rare adverse drug reaction. To date, a manual literature review identified only 91 reported cases. Clinical features may include cerebellar dysfunction, altered mental status and seizures.^{4,6} Our patient presented with symptoms of cerebellar dysfunction. A systematic review of case reports and case series involving 64 patients showed that 75% of affected patients had cerebellar dysfunction, 33% had altered mental status and 13% had seizures; 17% of patients had both cerebellar dysfunction and altered mental status; and one

Box 2: Naranjo Adverse Drug Reaction Probability Scale*†

Questionnaire	Yes	No	Do not know	Patient in this report‡
1. Are there previous conclusive reports on this reaction?	+1	0	0	Yes
2. Did the adverse event appear after the suspected drug was administered?	+2	-1	0	Yes
3. Did the adverse reaction improve when the drug was discontinued or a specific antagonist was administered?	+1	0	0	Yes
4. Did the adverse reaction reappear when the drug was readministered?	+2	-1	0	Do not know
5. Are there alternative causes (other than the drug) that could on their own have caused the reaction?	-1	+2	0	No
6. Did the reaction reappear when a placebo was given?	-1	+1	0	Do not know
7. Was the drug detected in the blood (or other fluids) in concentrations known to be toxic?	+1	0	0	Do not know
8. Was the reaction more severe when the dose was increased, or less severe when the dose was decreased?	+1	0	0	Do not know
9. Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	+1	0	0	Do not know
10. Was the adverse event confirmed by any objective evidence?	+1	0	0	Yes

*Scoring system for probability of an adverse drug reaction: ≥ 9 = definite, 5–8 = probable, 1–4 = possible, 0 = doubtful.

‡The patient in this report has a score of 7 (probable range).

patient presented with all three manifestations.⁶ Cases of metronidazole-induced encephalopathy have been reported with total cumulative doses of as low as 0.25 g to as high as 182 g, occurring over durations from one day to six months.^{3,6}

Pathophysiology of metronidazole-induced encephalopathy

The mechanism of neurologic injury in metronidazole-induced encephalopathy is postulated, but is not completely understood. Metronidazole has a large volume of distribution and readily crosses the blood–brain barrier.³ Experimental models show that intermediate metabolites of metronidazole can bind neuronal RNA, resulting in reversible axonal edema, as well as possibly modulating the expression of γ -aminobutyric acid.^{3,4,6,7}

Idiosyncratic drug reactions

In general, idiosyncratic drug reactions are unpredictable adverse effects that cannot be explained based on the pharmacology of a drug.^{8,9} Although the exact mechanism is still incompletely understood, these events are often believed to result from reactive metabolites of a drug and not the drug itself.^{8,9} They are dose-dependent reactions in individuals who are susceptible; however, there is no specific dose at which they occur in most patients.⁸ These reactions can affect any organ system, but commonly involve the liver, skin and bone marrow, and can be accompanied by fever.⁹ Because these events are idiosyncratic, monitoring for adverse reactions might not prevent onset, but will allow for earlier recognition, mitigation of consequences and prevention of re-exposure.

In addition to discontinuation of the drug, treatment is primarily supportive. This patient's metronidazole was discontinued, resulting in rapid clinical improvement. Most reported cases of metronidazole-induced encephalopathy have had good outcomes with resolution of signs, symptoms and MRI findings after drug cessation. Although the prognosis appears to be favourable overall, there are two case reports in which metronidazole-induced encephalopathy contributed to death,^{10,11} emphasizing the importance of timely recognition of a condition that is largely reversible.

Conclusion

This case highlights a rare adverse effect of a commonly prescribed medication. With an exposure history, adverse drug reactions should be on the differential diagnosis for any new-onset clinical signs and symptoms, but should be specifically considered when standard investigations are nondiagnostic.
