A complete list of the members of the 5 authorship groups appears at the end of the article.

Clinical presentation in persons infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) ranges from asymptomatic to the life-threatening respiratory distress that can occur with coronavirus disease 2019 (COVID-19).¹ Diagnosis of acute or new cases of SARS-CoV-2 infection at present relies upon molecular-based detection of viral RNA in upper or lower respiratory tract specimens, typically within 2–7 days after exposure.^{2,3} In this period, active viral shedding occurs, and individuals who are infected can transmit the virus to others. Although viral RNA may still be detected in respiratory and stool specimens of some people for many weeks after they have recovered, this does not appear to pose a transmission risk.^{4,5} Serological testing involves detection of antibodies specific to SARS-CoV-2 infection in blood, serum or plasma. The role of serology is limited in the diagnosis of acute COVID-19 because it usually takes a minimum of 7–14 days or more after symptom onset to develop a reliable and measurable SARS-CoV-2 antibody response.^{6,7} However, interest has arisen in the potential application of serological testing for purposes as wide-ranging as authorization of international travel, stratification of reinfection risk in workplaces and the reduction of public anxiety to facilitate resumption of economic activity.^{8,9} We review what is currently known regarding SARS-CoV-2 serological testing — a body of basic and clinical science that is still evolving (Box 1); consider its implications for clinical care, the development of appropriate services and test interpretation; and advise on appropriate use of serological testing for clinical and public health purposes.

What are the antibody responses to SARS-CoV-2?

The SARS-CoV-2 genome encodes 4 major structural proteins: surface or spike glycoprotein (S), envelope, membrane and nucleocapsid (N).¹⁰ Currently available serological tests detect antibodies to various epitopes on the S or N structural proteins.

KEY POINTS

- Multiple commercial assays for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) antibodies have been approved for use as serological tests by Health Canada, with some manufacturers claiming about 95% sensitivity and about 99.5% specificity.
- The detectable presence of SARS-CoV-2 antibodies has not yet been proven to confer meaningful or durable immunity to reinfection. Thus, serological testing should not be used to guide individual decisions about personal or occupational exposures, use of personal protective equipment and physical distancing.
- At present, clinical indications for serologic testing in health care settings are limited, and SARS-CoV-2 serological testing has no role in routine clinical care.
- Serological testing at this time should be focused on research concerning immunity to SARS-CoV-2 and population-level studies to inform public health responses to the Canadian coronavirus disease 2019 (COVID-19) epidemic.

The surface spikes are the “corona” observed on electron micrographs of coronaviruses; they play a critical role in viral pathogenesis, and thus studies have focused on antibodies to specific parts of the S glycoprotein. Each spike protein consists of 2 subunits: the S1 subunit binds to angiotensin-converting-enzyme-2 receptors on cells in multiple organs via its receptor-binding domain; and the S2 subunit mediates fusion between the virus and the cell membrane of the host. The S protein receptor-binding domain is an important vaccine and therapeutic target because a subset of antibodies targeting the receptor-binding domain appear to block viral binding and neutralize viral infectivity *in vitro*.^{11,12}

Box 1: Evidence used in this review

We searched PubMed for articles published from Jan. 1, 2020, to June 30, 2020, in English on severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), immune response, diagnostics and serology with the following medical subject headings terms: coronavirus disease 2019 (COVID-19), antibodies, serology, serologic test, diagnosis, point-of-care testing, immunoglobulin, immunoassay, enzyme-linked immunosorbent assay, immunity, humoral, cross-reaction, neutralization assay and multisystem inflammatory syndrome in children.

We identified additional articles through weekly searches of the LitCOVID database under the categories of “mechanism” and “diagnosis” from Mar. 15, 2020, to June 30, 2020.

We also identified relevant studies by consulting with Canadian experts and searching COVID-19 and SARS-CoV-2 preprints in *medRxiv* and *bioRxiv*. In addition, we regularly consulted the relevant guidelines and resources from international organizations including the World Health Organization, Health Canada, Public Health Agency of Canada, US Food and Drug Administration, US Centers for Disease Control and Prevention and Infectious Diseases Society of America, along with guidance generated by the participating Canadian organizations.

Figure 1 shows a schematic of the pattern of antibody response to SARS-CoV-2 infection. Although immunoglobulin M (IgM) and immunoglobulin A (IgA) antibodies are widely regarded to appear early during most acute viral infections, it is uncertain whether this occurs with SARS-CoV-2 infection.¹³ With COVID-19, similar to SARS and Middle East respiratory syndrome (MERS), both IgM and IgG antibodies appear at detectable levels concom-

itantly around 2–3 weeks after symptom onset or exposure.^{6,7,14,15} However, in some mild and asymptomatic cases, antibodies may not be detected at all, at least within the time scale as reported in some recent studies (< 46 d).^{15–17}

Commercially available assays target 1 or more of the 3 antibody isotypes (i.e., IgA, IgM or IgG) or total immunoglobulin. The 2 main types of commercial assays are described in Box 2. An updated list of approved clinical diagnostic tests for SARS-CoV-2 antibodies is available through the Health Canada website.²⁰ Although several laboratory-based immunoassays have been approved, there is insufficient evidence to support use of point-of-care testing devices for SARS-CoV-2 serology (see Box 2 for a description of these kits) and, at the time of writing, no SARS-CoV-2 serological point-of-care tests have received Health Canada approval for use.¹⁹ Effective use and interpretation of point-of-care tests will require consistent correlation of their results with approved laboratory-based tests, as well as secure supplies of kits that have consistent quality-assured performance.

What considerations affect the interpretation of SARS-CoV-2 serological tests?

Sensitivity, specificity and disease prevalence

The discriminative potential of a test is assessed by its clinical sensitivity and specificity. The sensitivity is a measure of the test’s ability to detect antibodies in matrices such as blood, serum or plasma of patients with SARS-CoV-2 infection (i.e., a true positive result). Specificity, on the other hand, is a measure of the test’s ability to correctly identify the absence of antibodies

Figure 1: Description and projection for the kinetics of antibody response to infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). With only a few months of experience to date, projections into years, although based on experience with other coronaviruses, must be regarded as speculative. Data on immunoglobulin A (IgA) responses are still emerging. Note: IgM = immunoglobulin M, IgG = immunoglobulin G.

in an individual who has not been infected (i.e., a true negative result). At present, Health Canada recommends a target specificity of 98% or higher, and the minimum required for consideration of approval is 95%.²¹ Sensitivity and specificity are inherent elements of test performance, but the predictive value of any test depends on the prevalence of the infection within a given population. For example, if the disease prevalence in the popula-

Box 2: Approaches to detecting antibodies for severe acute respiratory syndrome coronavirus 2

Testing matrices

- The tests listed here are typically used to detect antibody in blood sources.
- Laboratory-based immunoassays and specialized neutralization tests rely on blood matrices (serum or plasma). Point-of-care tests use blood from finger pricks (or heel pricks as applicable).
- Finger pricks can also be used to create dried blood spots that can be conveniently transported for laboratory-based immunoassays. Early results for dried blood spot testing results are promising, but insufficient evidence currently exists to support dried blood spot testing for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Comprehensive validation against results of tests based on venipuncture blood draws is ongoing worldwide.
- The consistency and interpretation of antibody detection from sources other than blood, such as saliva, is still uncertain.

Types of tests

- Laboratory-based immunoassays involve plate-based tests (enzyme-linked immunosorbent assays [ELISAs]) or chemiluminescent immunoassays (CLIAs) on automated high-throughput instruments. With most immunoassays, the signal produced by the assay correlates with the level of antibody detected in the patient's sample. Cross-reactions with other coronaviruses are uncommon but do occur. For laboratory-based tests, venipuncture and transport to the testing laboratory is typically required. Commercially available immunoassays are semiquantitative (i.e., use a cut-off to determine reactive [positive] versus nonreactive [negative] results).
- Rapid test cassettes or lateral flow tests are often referred to as point-of-care tests. These tests are typically easy to use, require only a small amount of blood matrix (e.g., from a finger prick), do not require specialized equipment or expertise and have rapid turnaround times (10–15 min).¹⁸ Most can detect immunoglobulin M and immunoglobulin G separately or in combination. However, such assays are qualitative, performance varies substantially and none have been approved by Health Canada to date. There is no current indicated use for point-of-care tests.¹⁹
- Neutralization tests are considered the gold standard for antibody detection because of their high sensitivity and specificity but are not widely available. Laboratory-based and point-of-care immunoassays are “binding antibody assays” (i.e., they detect binding of antibody from patient blood to SARS-CoV-2 antigens). In contrast, neutralization assays measure antibody-mediated inhibition of viral entry into cells *in vitro*. These tests require specialized expertise and laboratory containment facilities (containment level 3 for SARS-CoV-2), and have limited throughput. However, pseudovirus-based neutralization assays can detect neutralizing antibody to SARS-CoV-2 using engineered noninfectious virus strains and can be performed in containment level 2 laboratories.

tion is only 1%, even a highly specific diagnostic test (99% specificity or only 1 false-positive result out of 100 patient results) would be predicted to lead to roughly 1 false-positive result for every true positive result.^{9,22}

In Canada, the baseline prevalence of SARS-CoV-2 infection as of July 9, 2020, was estimated at 0.3%, based on 106 805 confirmed cases of COVID-19.²³ However, the number of Canadians infected is likely many times higher than indicated by the number of confirmed cases for several reasons. Current nucleic acid testing has moderate sensitivity, and tests performed in patients with infection may have returned a negative result in some cases. Furthermore, testing indications and coverage have varied over time and by region, and some people with SARS-CoV-2 infection do not show symptoms; therefore, many people who were infected may not have requested or qualified for testing. The prevalence of asymptomatic infection measured in other jurisdictions ranges widely depending on the target population tested, geographic location and age of the patients.^{14,24–27}

We posit that the prevalence in most Canadian locations is likely low enough that very small reductions in test specificity will drive up the proportion of false positives that are reported. This can be corrected post hoc in population-level estimates of the prevalence of SARS-CoV-2 infections but creates problems in applying serology results at the individual level — a challenge compounded by biological uncertainties.

Correlation of SARS-CoV-2 antibodies with virus neutralization

Commercially available serological assays detect and semi-quantitatively determine the amount of antibody binding to various SARS-CoV-2 antigens. (Quantitation may be valuable when a rising level suggests recent infection and associated positive seroconversion.) Depending on the antigen target used, the bound antibodies detected may correlate with detection of neutralizing antibodies that, as noted above, are antibodies that block viral binding and neutralize viral infection *in vitro* (hence the term, neutralizing antibodies). Neutralizing antibodies may provide a better indication of immunity, but there is ongoing debate as to whether neutralizing antibodies are the primary mechanism of immune protection against SARS-CoV-2 infection.^{22,28–30} Instead, a cell-mediated immune response, known to be a key element in viral control for SARS-CoV-1 and MERS-CoV,^{31–33} may be more relevant. Therefore, further studies are required to evaluate the correlation of commercial assays for SARS-CoV-2 antibodies with neutralization capacity, the potential for antibody-dependent cell-mediated immune responses and seroprotection.^{34,35}

Duration of antibody response

In mild and asymptomatic cases, antibody responses may not consistently develop or reach levels sufficient to be detectable by antibody tests.³⁶ Research continues on the extent and duration of antibody responses in the context of infections ranging from asymptomatic to severe, and across different populations, ages, genetic backgrounds and comorbidities. Antibody levels to

coronaviruses diminish over time.^{37,38} Persistence of measurable neutralizing antibodies for at least a year has been reported in patients who have recovered from MERS-CoV and SARS-CoV-1 illness, despite declines in titres.^{39,40} However, studies evaluating the immunological response to SARS-CoV-2 have suggested that a substantial proportion of asymptomatic patients are IgG negative during the convalescent phase of infection,³⁶ and evidence is emerging that neutralizing antibodies to SARS-CoV-2 decrease in convalescent patients within 2–3 months after infection.^{36,41} In contrast, multiyear persistence of memory T-cell responses has been reported for both MERS-CoV and SARS-CoV-1,^{32,33} which suggests that waning antibody titres may not portend loss of immunity. The relation between measured antibodies and durability of protection therefore remains unclear.

Serological test positivity and infectiousness

A positive antibody result cannot be equated to a noninfectious state. Particularly for non-neutralizing antibodies, the presence of antibodies does not preclude active viral shedding through respiratory secretions.^{42,43} Thus, factors such as symptom onset, symptom resolution and days since onset or resolution should guide advice on infectivity.

What are the implications for practitioners and policy-makers?

Consider test performance

Laboratories should strive to implement SARS-CoV-2 serologic tests that have manufacturer-claimed sensitivity of 95% or more and specificity of 99.5% or more based on specimens obtained 14 days or more after onset of symptoms or a positive result for an RNA test. Serological testing in a real-world setting is necessary to confirm that the tests perform as claimed. To maximize specificity in populations with low pretest probability of disease (i.e., low community prevalence), it may be necessary to use orthogonal testing so that those patients with a positive result for 1 test are routinely retested with a second test to confirm the result.

When interpreting serological results, laboratories may need to consider time since onset of symptoms or time since exposure to SARS-CoV-2, if they are known. Clinical laboratories and ordering physicians also need to consider the pretest probability of a positive or negative result given the testing location and patient population (e.g., higher likelihood of a positive result in a hospital setting versus an outpatient seroprevalence screen).

Additional research studies of the performance of serology tests will be required with individuals in different age groups, at different times after exposure and to determine duration of detectable antibody after infection.

When and who to test

At present, use of SARS-CoV-2 serological testing should focus on informing the public health response to the Canadian epidemic rather than on estimating any individual's current or future susceptibility to infection. Serological testing should be reserved primarily for clinical research and population-level assessments of the prevalence of past infection with SARS-CoV-2.

Box 3: Use of serology in suspected multisystem inflammatory syndrome in children and adolescents temporally related to coronavirus disease 2019

- Case definitions for multisystem inflammatory syndrome in children (MIS-C) have been outlined by several organizations including the World Health Organization, Centers for Disease Control and Prevention, Royal College of Paediatrics and Child Health in the United Kingdom and the Canadian Paediatric Society,^{48–51} and include the use of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) serology.
- Case series have reported high percentages of patients with positive results for SARS-CoV-2 serology testing, with lower rates of positivity for throat swabs and stool samples on polymerase chain reaction testing.^{52–54}
- Several Canadian provinces are in the process of adopting these case criteria and have identified MIS-C as a notifiable disease, which requires case reporting to local public health authorities.^{55–57}
- Despite the inclusion of serological testing in the MIS-C case definitions, the performance of serological tests in children and in patients with MIS-C remains poorly characterized.
- More studies are needed, including validation studies of SARS-CoV-2 antibody assays in children and in suspected MIS-C.

As outlined previously, serological testing is neither adequate nor appropriate for use as the primary tool for diagnosis of infection or confirmation of noninfectivity. In other words, the current state of knowledge would not support having broadly available SARS-CoV-2 antibody tests. In the absence of a positive RNA test or evidence of seroconversion (as measured by a rising antibody level over time), serology should not be used to diagnose acute SARS-CoV-2 infection. On rare occasions, serological testing may be useful as an adjunct diagnostic test when molecular testing is repeatedly negative but clinical suspicion is high and symptoms persist.^{7,13,44–46} In such cases, the time since exposure (if known) or since symptom onset should be considered as seropositivity occurs only 7–14 or more days after symptom onset.

Serological testing may assist in the assessment of patients who present with atypical clinical manifestations such as inflammatory syndromes (e.g., multisystem inflammatory disorder in children and adolescents, COVID toes or unexplained thrombosis).^{47,48} Box 3 discusses antibody testing in the context of multisystem inflammatory syndrome in children and adolescents, based on limited current evidence.^{13,49–54}

How to report the results of serological tests

A recent United Kingdom report⁵⁸ showed variability in the clinical interpretation of SARS-CoV-2 serology results especially with respect to inferring immunity and the infectious status of individuals. Consistent messaging and avoiding misinterpretation of serology test results depends on harmonized reporting across laboratories combined with proactive communication by laboratory staff, medical microbiologists and infectious disease practitioners. Box 4 provides suggestions for some interpretive wording for interim use by clinical and public health laboratories for reporting SARS-CoV-2 serology.

Box 4: Suggestions for the reporting of test results by clinical laboratories (include as appended comments)

Reporting positive/reactive results

- Presence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) antibody indicates current or previous infection. False-positive results may occur because of cross-reacting antibody or other causes. Currently, it is unknown whether antibodies indicate protective immunity and for how long.
- Presence of SARS-CoV-2 antibody should not be used to infer the infectious status of an individual or immunity.

Reporting negative/nonreactive results

- Nonreactive results do not rule out acute or previous SARS-CoV-2 infection.
- Absence of SARS-CoV-2 antibody should not be used to infer the infectious status of an individual or immunity.

Reporting inconclusive/indeterminate results

- An inconclusive result neither rules in nor rules out previous SARS-CoV-2 infection.

Potential uses of SARS-CoV-2 serology from a public health and research perspective

At present, based on the evidence we have considered, serological test results should not be used to guide patient-level decision-making on measures for infection control, including the use of personal protective equipment, timing of return to work or local physical-distancing policies.

However, seroprevalence studies of SARS-CoV-2 may be used to estimate rates of exposure and the geographic transmission of the virus within communities and populations, as well as within facilities, workplaces and households over time. This information may be used by epidemic modellers to help guide public health policies, by vaccine program planners to help set priorities and by front-line public health practitioners to determine which communities or congregate settings show minimal past exposure to SARS-CoV-2 and, therefore, may be at higher risk of rapid spread. At the interface of clinical and public health applications, while the diagnostic role of antibody testing is strictly adjunctive, seroprevalence studies may be useful in contact tracing when RNA tests are indeterminate.

Longitudinal seroprevalence studies may provide information on the nature and durability of antibody responses in patients with confirmed infection. The aim of such studies may be to determine if previous COVID-19 infection and seropositivity is associated with protection from subsequent reinfection; specialized serology tests, such as neutralization assays, will be particularly useful in this context. Likewise, serological screening of donated blood may reveal which blood samples contain adequate levels of neutralizing antibody to allow for their use in randomized controlled trials that investigate the effectiveness of pooled convalescent plasma treatment for patients with severe COVID-19.

Studies of vaccine effectiveness for SARS-CoV-2 may use serological testing results as a marker of immunity in cohort studies that explore correlates of protection and reinfection risk.

Conclusion

Given measurement and interpretive uncertainties of the tests, the clinical indications for SARS-CoV-2 serological testing are limited, with only a few exceptions. The tests will be useful in diverse research contexts and for policy-making in public health but should not be rolled out for general clinical use based on current evidence. Careful interpretation and reporting of test results is important. The current state of knowledge does not permit definitive inferences about immunity and likelihood of reinfection based on the results of serological testing, and testing cannot, therefore, be used to inform individual-level decisions on changing occupational exposure, the use of personal protective equipment, recommendations on physical distancing by members of the public or advice on international travel.

Competing interests: Paul Van Caesele is the director of the Cadham Provincial Public Health Laboratory (Manitoba Health). Mel Krajden has received grants paid to his institution from Roche, Hologica and Siemens. No other competing interests were declared. For competing interests of members of the 5 authorship groups, see Appendix 1, available at <https://www.cmaj.ca/lookup/doi/10.1503/cmaj.201588/tab-related-content>

This article has been peer reviewed.

Affiliations: Cadham Provincial Public Health Laboratory (Van Caesele), Winnipeg, Man.; Dynacare (Bailey), Brampton, Ont.; Division of Pediatric Infectious Diseases (Forgie), Department of Pediatrics, University of Alberta, Edmonton, Alta.; Alberta Precision Laboratories (Dingle), Edmonton, Alta.; and Department of Pathology and Laboratory Medicine (Krajden), University of British Columbia, Vancouver, BC.

Contributors: All of the authors contributed to the conception and design of the review; revised the manuscript, which was first drafted by Dana Bailey and Mel Krajden, for important intellectual content; gave final approval of the version to be published; and agreed to be accountable for all aspects of the work. Paul Van Caesele serves as co-chair of the Canadian Public Health Laboratory Network. Dana Bailey serves as the designated corresponding author for the Canadian Society of Clinical Chemists COVID-19 Significant Interest Working Group. Sarah Forgie serves as president of the Association of Medical Microbiology and Infectious Disease Canada. Tanis Dingle serves as president of the Canadian Association for Clinical Microbiology and Infectious Diseases. Mel Krajden leads the Testing Working Group of the COVID-19 Immunity Task Force.
